Chapter 10

Synaptic transmission and artificial spiking cells

In NEURON, a cell model is a set of differential equations. Network models consist of cell models and the connections between them. Some forms of communication between cells, e.g. graded synapses, gap junctions, and ephaptic interactions, require more or less complete representations of the underlying biophysical mechanisms. In these cases, coupling between cells is achieved by adding terms that refer to one cell's variables into equations that belong to a different cell. The first part of this chapter describes the POINTER syntax that makes this possible in NEURON.

The same approach can be used for detailed mechanistic models of spike-triggered transmission, which entails spike initiation and propagation to the presynaptic terminal, transmitter release, ligand-receptor interactions on the postsynaptic cell, and somatodendritic integration. However, it is far more efficient to use the widespread practice of treating spike propagation from the trigger zone to the synapse as a delayed logical event. The second part of this chapter tells how the NetCon (network connection) class supports this event-based style of communication.

In the last part of this chapter, we use event-based communication to simplify representation of the neurons themselves, creating highly efficient implementations of artificial spiking cells, e.g. integrate and fire "neurons." Artificial spiking cells are very convenient sources of spike trains for driving synaptic mechanisms attached to biophysical neuron models. Networks that consist entirely of artificial spiking cells run hundreds of times faster than their biophysical counterparts, so they are particularly suitable for prototyping network models. They are also excellent tools in their own right for studying the functional consequences of network architectures and synaptic plasticity rules. In **Chapter 11** we demonstrate network models that involve various combinations of biophysical and artificial neuron models.

Modeling communication between cells

Experiments have demonstrated many kinds of interactions between neurons, but for most cells the principal avenues of communication are gap junctions and synapses. Gap junctions and synapses generate localized ionic currents, so in NEURON they are represented by point processes (see **Point processes** in **Chapter 5**, and **Example 9.2: a localized shunt** and **Example 9.3: an intracellular stimulating electrode** in **Chapter 9**).

The point processes used to represent gap junctions and synapses must produce a change at one location in the model that depends on information (membrane potential,

calcium concentration, the occurrence of a spike) from some other location. This is in sharp contrast to the examples we discussed in **Chapter 9**, all of which are "local" in the sense that an instance of a mechanism at a particular location on the cell depends only on the

Models with LONGITUDINAL_DIFFUSION might also be considered "nonlocal," but their dependence on concentration in adjacent segments is handled automatically by the NMODL translator.

STATES and PARAMETERS of that model *at that location*. They may also depend on voltage and ionic variables, but these also are *at that location* and automatically available to the model. To see how to do this, we will examine models of graded synaptic transmission, gap junctions, and spike-triggered synaptic transmission.

Example 10.1: graded synaptic transmission

A minimal conceptual model of graded synaptic transmission is that neurotransmitter is released continuously at a rate that depends on something in the presynaptic terminal, and that this causes some change in the postsynaptic cell. For the sake of discussion, let's say this something is $[Ca^{2+}]_{pre}$, the concentration of free calcium in the presynaptic terminal. We will also assume that the transmitter changes an ionic conductance in the postsynaptic cell.

Figure 10.1. Membrane potential in the immediate neighborhood of a postsynaptic conductance depends on the synaptic current (I_s) , the currents through the local membrane capacitance and ionic conductances $(I_c \text{ and } I_{ion})$, and the axial current arriving from adjacent regions of the cell (I_a) .

From the standpoint of the postsynaptic cell, a conductance-change synapse might look like Fig. 10.1, where g_s , E_s , and I_s are the synaptic conductance, equilibrium potential, and current, respectively. The effect of graded synaptic transmission on the postsynaptic cell is expressed in Equation 10.1.

$$C_m \frac{dV_m}{dt} + I_{ion} = I_a - (V_m - E_s) \cdot g_s([Ca^{2+}]_{pre})$$
 Eq. 10.1

This is the charge balance equation for the electrical vicinity of the postsynaptic region. The terms on the left hand side are the usual local capacitive and ionic transmembrane currents. The first term on the right hand side is the current that enters the postsynaptic region from adjacent parts of the cell, which NEURON takes care of automatically. The second term on the right hand side expresses the effect of the ligand-gated channels. The current through these channels is the product of two factors. The first factor is merely the local electrochemical gradient for ion flow. The second factor is a conductance term that depends on the calcium concentration at some other location.

We already know that a localized conductance is implemented in NEURON with a point process, and that such a mechanism is automatically able to access all the local variables that it needs (in this case, the local membrane potential and the synapse's equilibrium potential). But the calcium concentration in the presynaptic terminal is nonlocal, and that poses a problem; furthermore, it is likely to change with every fadvance().

We could try inserting a hoc statement like this into the main computational loop

somedendrite.syn.capre = precell.bouton.cai(1)

At each time step, this would update the variable capre in the synaptic mechanism syn attached to the postsynaptic section somedendrite, making it equal to the free calcium concentration cai at the 1 end of the bouton section in the presynaptic cell precell. However, this statement would have to be reinterpreted at each fadvance(), which might slow down the simulation considerably.

If what happens to the postsynaptic cell depends on the moment-to-moment details of what is going on in the presynaptic terminal, it is far more efficient to use a POINTER variable (see Listing 10.1). In NMODL, a POINTER variable holds a reference to another variable. The specific reference is defined by a hoc statement, as we shall see below.

```
: Graded synaptic transmission
NEURON {
  POINT_PROCESS GradSyn
  POINTER capre
  RANGE e, k, g, i
  NONSPECIFIC CURRENT i
}
UNITS {
  (nA) = (nanoamp)
  (mV) = (millivolt)
  (uS) = (microsiemens)
  (molar) = (1/liter)
  (mM) = (millimolar)
}
PARAMETER {
  e = 0 (mV) : reversal potential
  k = 0.02 (uS/mM3)
}
```

POINTER variables are not limited to point processes. Distributed mechanisms can also use POINTERs, although possibly for very different purposes.

```
ASSIGNED {
    v (mV)
    capre (mM) : presynaptic [Ca]
    g (uS)
    i (nA)
}
BREAKPOINT {
    g = k*capre^3
    i = g*(v - e)
}
```

Listing 10.1. gradsyn.mod

The NEURON block

The POINTER statement in the NEURON block declares that capre refers to some other variable that may belong to a noncontiguous segment, possibly even in a different section; below we show how to attach this to the free calcium concentration in a presynaptic terminal. The synaptic strength is not specified by a peak conductance, but in terms of a "transfer function scale factor" k, which has units of (μ S/mM³).

The BREAKPOINT block

The synaptic conductance g is proportional to the cube of capre and does not saturate. This is similar to the calcium dependence of synaptic conductance in a model described by De Schutter et al. [, 1993 #717].

Usage

After creating a new instance of the GradSyn point process, we link its POINTER variable to the variable at some other location we want it to follow with hoc statements, e.g.

```
objref syn
somedendrite syn = new GradSyn(0.8)
setpointer syn.cp, precell.bouton.cai(0.5)
```

The second statement attaches an instance of the GradSyn mechanism, called syn, to somedendrite. The third statement uses setpointer to assert that the synaptic conductance of syn will be governed by cai in the middle of a section called bouton that is part of cell precell. Of course this assumes that the presynaptic section precell.bouton contains a calcium accumulation mechanism.

Figure 10.2 shows simulation results from a model of graded synaptic transmission. In this model, the presynaptic terminal precell is a 1 µm diameter hemisphere with voltage-gated calcium current cachan (cachan.mod in c:nrnxx\examples\nrniv\nmodl under UNIX) and a under MSWindows or nrn-x.x/share/examples/nrniv/nmodl under UNIX) and a calcium accumulation mechanism that includes diffusion, buffering, and a pump (cdp, discussed in **Example 9.9: a calcium pump**). The postsynaptic cell is a passive single compartment with surface area 100 µm², $C_m = 1 \mu f/cm^2$, and $\tau_m = 30$ ms. A GradSyn

synapse with transfer function scale factor $k = 0.2 \,\mu\text{S/mM}^3$ is attached to the postsynaptic cell, and presynaptic membrane potential is driven between -70 and -30 mV by a sinusoid with a period of 400 ms. The time course of presynaptic [Ca]_i and synaptic conductance show clipping of the negative phases of the sine wave; the postsynaptic membrane potential shows less clipping because of filtering by membrane capacitance.

Figure 10.2. Graded synaptic transmission. Top two graphs: Presynaptic membrane potential preterm.v was "clamped" to -70-20cos $(2\pi t/400)$ mV, producing a periodic increase of $[Ca]_i$ (preterm.cai is the concentration just inside the cell membrane) with clipping of the negative peaks. Bottom two graphs: The synaptic conductance GradSyn[0].g shows even more clipping of the negative phases of the sinusoid, but membrane capacitance smoothes the time course of postsynaptic membrane potential.

Example 10.2: a gap junction

The current that passes through a gap junction depends on the moment-to-moment fluctuations of voltage on both sides of the junction. This can be handled by a pair of point processes on the two sides that use POINTERS to monitor each other's voltage, as in

```
section1 gap1 = new Gap(x1)
section2 gap2 = new Gap(x2)
setpointer gap1.vpre, section2.v(x2)
setpointer gap2.vpre, section1.v(x1)
```

Conservation of charge requires the use of two point processes: one drains current from one side of the gap junction, and the other delivers an equal current to the other side.

Listing 10.2 presents the NMODL specification of a point process that can be used to implement ohmic gap junctions.

```
NEURON {
   POINT_PROCESS Gap
   POINTER vgap
   RANGE r, i
   NONSPECIFIC_CURRENT i
}
PARAMETER { r = lel0 (megohm) }
ASSIGNED {
   v (millivolt)
   vgap (millivolt)
   i (nanoamp)
}
BREAKPOINT { i = (v - vgap)/r }
Listing 10.2. gap.mod
```

This implementation can cause spurious oscillations if the coupling between the two voltages is too tight (i.e. if the resistance r is too low) because it degrades the Jacobian matrix of the system equations. While it does introduce off-diagonal terms to couple the nodes on either side of the gap junction, it fails to add the conductance of the gap junction to the terms on the main diagonal. The result is an *approximate* Jacobian, which makes numeric integration effectively a modified Euler method, instead of the fully implicit or Crank-Nicholson methods which are numerically more robust. Consequently, results are satisfactory only if coupling is loose (i.e. if r is large compared to the total conductance of the other ohmic paths connected to the affected nodes). If oscillations do occur, their amplitude can be reduced by decreasing dt, and they can be eliminated by using CVODE. In such cases, it may be preferable to implement gap junctions is with the LinearMechanism class (e.g. by using the LinearCircuitBuilder), which sets up the diagonal and off-diagonal terms of the Jacobian properly so that simulations are completely stable.

Usage

The following hoc code use this mechanism to set up a model of a gap junction between two cells. The Gap mechanisms allow current to flow between the internal node at the 1 end of a and the internal node at the 0 end of b.

```
create a,b
access a
forall {nseg=10 L=1000 diam=10 insert hh}
```

```
objref g[2]
for i=0,1 {
  g[i] = new Gap()
  g[i].r = 3
}
a g[0].loc(0.9999) // just inside "distal" end of a
b g[1].loc(0.0001) // just inside "proximal" end of b
setpointer g[0].vgap, b.v(0.0001)
setpointer g[1].vgap, a.v(0.9999)
```

Modeling spike-triggered synaptic transmission: an event-based strategy

Prior to NEURON 4.1, model descriptions of synaptic transmission could only use POINTER variables to obtain their presynaptic information. This required a detailed piecing together of individual components that was acceptable for models with only a few synapses. Models of larger networks required users to exert considerable administrative effort to create mechanisms that handle synaptic delay, exploit potentially great simulation efficiencies offered by simplified models of synapses, and maintain information about network connectivity.

The experience of NEURON users in creating special strategies for managing network simulations (e.g. [Destexhe, 1994 #267][Lytton, 1996 #206]) stimulated the development of NEURON's network connection (NetCon) class and event delivery system. Instances of the NetCon class manage the delivery of presynaptic "spike" events to synaptic point processes via the event delivery system. This works for all of NEURON's integrators, including the local variable time step method in which each cell is integrated with a time step appropriate to its own state changes. Model descriptions of synapses never need to queue events, and there is no need for heroic efforts to make them work properly with adaptive integration. These features offer enormous convenience to users who are interested in models that involve synaptic transmission at any level of complexity from single cell to large networks.

Conceptual model

In its most basic form, the physical system that we want to represent consists of a presynaptic neuron with a spike initiation zone that gives rise to an axon, which leads to a terminal that makes a synaptic connection onto a postsynaptic cell (Fig. 10.3). Our conceptual model of spike-triggered transmission is that arrival of a spike at the presynaptic terminal has some effect (e.g. a conductance change) in the postsynaptic cell that is described by a differential equation or kinetic scheme. Details of what goes on at the spike initiation zone are assumed to be unimportant--all that matters is whether a spike has, or has not, reached the presynaptic terminal. This conceptual model lets us take advantage of special features of NEURON that allow extremely efficient computation.

Figure 10.3. Cartoon of a synaptic connection (filled circle) between a presynaptic cell pre and a postsynaptic cell post.

A first approach to implementing a computational representation of our conceptual model might be something like the top of Fig. 10.4. We would monitor membrane potential at the presynaptic terminal for spikes (watch for threshold crossing). When a spike is detected, we wait for an appropriate delay (latency of transmitter release plus diffusion time) and then notify the synaptic mechanism that it's time to go into action. For this simple example, we have assumed that synaptic transmission simply causes a conductance change in the postsynaptic cell. It is also possible to implement more complex mechanisms that include representations of processes in the presynaptic terminal (e.g. processes involved in use-dependent plasticity).

We can speed things up a lot by leaving out the axon and presynaptic terminal entirely, i.e. instead of computing the propagation of the action potential along the axon, just monitor the spike initiation zone. Once a spike occurs, we wait for a total delay equal to the sum of the conduction latency and the synaptic latency, and then activate the postsynaptic conductance change (Fig. 10.4 bottom).

Figure 10.4. Computational implementation of a model of spike-triggered synaptic transmission. Top: The basic idea is that a presynaptic spike causes some change in the postsynaptic cell. Bottom: A more efficient version doesn't bother computing conduction in the presynaptic axon.

The NetCon class

Let's step back from this problem for a moment and think about the bottom diagram in Fig. 10.4. The "spike detector" and "delay" in the middle of this diagram are the seed of an idea for a general strategy for dealing with synaptic connections. In fact, the NetCon object class is used to apply this strategy in defining the synaptic connection between a source and a target.

A NetCon object connects a presynaptic variable, such as voltage, to a target point process (here a synapse) with arbitrary delay and weight. If the presynaptic variable crosses threshold in a positive direction at time t, then at time t+delay a special NET_RECEIVE procedure in the target point process is called and receives the weight information. Each NetCon can have its own threshold, delay, and weight, i.e. these parameters are stream-specific. The only constraint on delay is that it be nonnegative. There is no limit on the number of events that can be "in the pipeline," and there is no loss of events under any circumstances. Events always arrive at the target at the interval delay after the time they were generated.

When you create a NetCon object, at a minimum you must specify the source variable and the target. The source variable is generally the membrane potential of the currently accessed section, as shown here. The target is a point process that contains a NET_RECEIVE block (see Listing 10.3 below).

```
section netcon = new NetCon(&v(x), target, thresh, del, wt)
```

Threshold, delay, and weight are optional; their defaults are shown here, and they can be specified after the NetCon object has been constructed.

<i>netcon</i> .threshold = 10	11	mV
<i>netcon</i> .delay = 1	11	ms
<i>netcon</i> .weight = 0	11	uS

The weight associated with a NetCon object is actually the first element of a weight vector. The number of elements in the weight vector depends on the number of arguments in the NET_RECEIVE statement of the NMODL source code that defines the point process. We will return to this in **Example 10.5: use-dependent synaptic plasticity** and **Example 10.6: saturating synapses**.

NEURON's event-based approach to implementing communication between cells reduces the computational burden of network simulations tremendously, because it supports efficient, unlimited divergence and convergence (fan-out and fan-in). To understand why, first consider divergence. What if a presynaptic cell projects to multiple postsynaptic targets (Fig. 10.5 top)? Easy enough--just add a NetCon object for each target (Fig. 10.5 bottom). This is computationally efficient because threshold detection is done on a "per source" basis, rather than a "per NetCon" basis. That is, if multiple NetCons have the same source with the same threshold, they all share a single threshold detector. The source variable is checked only once per time step and, when it crosses threshold in the positive direction, events are generated for each connecting NetCon object. Each of these NetCons can have its own weight and delay, and the target mechanisms can belong to different classes.

Now consider convergence. Suppose a neuron receives multiple inputs that are anatomically close to each other and of the same type (Fig. 10.6 top). In other words, we're assuming that each synapse has its postsynaptic action through the same kind of mechanism (i.e. it has identical kinetics, and (in the case of conductance-change synapses) the same equilibrium potential). We can represent this by connecting multiple NetCon objects to the same postsynaptic point process (Fig. 10.6 bottom). This yields large efficiency improvements because a single set of synaptic equations can be shared by many input streams (one input stream per connecting NetCon instance). Of course, these synapses can have different strengths and latencies, because each NetCon object has its own weight and delay.

Figure 10.5. Efficient divergence. Top: A single presynaptic neuron projects to two different target synapses. Bottom: Computational model of this circuit uses multiple NetCons with a single threshold detector that monitors a common source.

Figure 10.6. Efficient convergence. Top: Two different presynaptic cells make synaptic connections of the same class that are electrically close to each other. Bottom: Computational model of this circuit uses multiple NetCons that share a single postsynaptic mechanism (single equation handles multiple input streams).

Having seen the rationale for using events to implement models of synaptic transmission, we are ready to examine some point processes that include a NET_RECEIVE block and can be used as synaptic mechanisms in network models.

Example 10.3: synapse with exponential decay

Many kinds of synapses produce a synaptic conductance that increases rapidly and then declines gradually with first order kinetics, e.g. AMPAergic excitatory synapses. This can be modeled by an abrupt change of conductance, which is triggered by arrival of an event, and then decays with a single time constant.

The NMODL code that implements such a mechanism is shown in Listing 10.3. This mechanism is similar to NEURON's built in ExpSyn. Calling it ExpSyn1 allows us to test and modify it without conflicting with NEURON's built-in ExpSyn.

The synaptic conductance of this mechanism summates not only when events arrive from a single presynaptic source, but also when they arrive from different places (multiple input streams). This mechanism handles both situations by defining a single conductance state g which is governed by a differential equation whose solution is

 $g(t) = g(t_0) e^{(t-t_0)/\tau}$, where $g(t_0)$ is the conductance at the time of the most recent

event.

```
: expsyn1.mod
NEURON {
 POINT_PROCESS ExpSyn1
RANGE tau, e, i
  NONSPECIFIC CURRENT i
}
PARAMETER {

  i = g^*(v - e)
}
```

DERIVATIVE state { g' = -g/tau }
NET_RECEIVE(weight (microsiemens)) {
 g = g + weight
}

Listing 10.3. expsyn1.mod

The breakpoint block

The BREAKPOINT block of this mechanism is its main computational block. This contains the SOLVE statement that tells how states will be integrated. The cnexp method is used because the kinetics of ExpSyn1 are described by a differential equation of the form y' = f(y), where f(y) is linear in y (see also **The DERIVATIVE block** in **Example 9.4: a voltage-gated current** in **Chapter 9**). The BREAKPOINT block ends with an assignment statement that sets the value of the synaptic current.

The DERIVATIVE block

The DERIVATIVE block contains the differential equation that describes the time course of the synaptic conductance g: a first order decay with time constant tau.

The NET_RECEIVE block

The NET_RECEIVE block contains the code that specifies what happens in response to presynaptic activation. This is called by the NetCon event delivery system when an event arrives at this point process.

So suppose we have a model with an ExpSyn1 point process that is the target of a NetCon. Imagine that the NetCon detects a presynaptic spike at time t. What happens next?

ExpSyn1's conductance g continues to follow a smooth exponential decay with time constant tau until time t+delay, where delay is the delay associated with the NetCon object. At this point, an event is delivered to the ExpSyn1. Just before

As we mentioned in **Chapter 9**, earlier versions of NEURON had to change g with a state_discontinuity() statement. This is no longer necessary.

entry to the NET_RECEIVE block, NEURON makes all STATES, v, and values assigned in the BREAKPOINT block consistent at t+delay. Then the code in the NET_RECEIVE block is executed, making the synaptic conductance suddenly jump up by the amount specified by the NetCon's weight.

Usage

Suppose we wanted to set up a synaptic connection between two cells using an ExpSyn1 mechanism, as in Fig. 10.7. This could be done with the following hoc code, which also illustrates the use of a List of NetCon objects as a means for keeping track of the synaptic connections in a network.

Figure 10.7. Schematic of a synaptic connection between two cells.

```
// keep connectivity in a list of NetCon objects
objref ncl
ncl = new List()
```

```
// attach an ExpSyn1 point process called syn
// to the 0.3 location on dend[3] of cell[5]
objref syn
cell[5].dend[3] syn = new ExpSyn1(0.3)
```

Figure 10.8. Simulation results from the model shown in Fig. 10.6. Note stream-specific synaptic weights and temporal summation of synaptic conductance and membrane potential.

Figure 10.8 shows results of a simulation of two input streams that converge onto a single ExpSyn1 attached to a postsynaptic cell, as in the diagram at the top of Fig. 10.6. The presynaptic firing times are indicated by the rasters labeled precell[0] and precell[1]. The synaptic conductance and postsynaptic membrane potential (middle and bottom graphs) display stream-specific synaptic weights, and also show temporal summation of inputs within an individual stream and between inputs on multiple streams.

Example 10.4: alpha function synapse

With a few small changes, we can extend ExpSyn1 to implement an alpha function synapse. We only need to replace the differential equation with the two state kinetic scheme

```
STATE { a (microsiemens) g (microsiemens) }
KINETIC state {
    ~ a <-> g (1/tau, 0)
    ~ g -> (1/tau)
}
```

and change the NET_RECEIVE block to

```
NET_RECEIVE(weight (microsiemens)) {
    a = a + weight*exp(1)
}
```

The factor exp(1) = e is included so that an isolated event produces a peak conductance of magnitude weight, which occurs at time tau after the event. Since this mechanism involves a KINETIC block instead of a DERIVATIVE block, we must also change the integration method specified by the SOLVE statement from cnexp to sparse.

The extra computational complexity of using a kinetic scheme is offset by the fact that, no matter how many NetCon streams connect to this model, the computation time required to integrate STATE g remains constant. Some increase of efficiency can be gained by recasting the kinetic scheme as two linear differential equations

```
DERIVATIVE state {
..a' = -a/taul
..b' = -b/tau
..g = b - a
}
```

which are solved by the cnexp method (this is what NEURON's built in Exp2Syn mechanism does). As taul approaches tau, g approaches an alpha function (although the factor by which weight must be multiplied approaches infinity; see factor in the next example). Also, there are now two state discontinuities in the NET_RECEIVE block

```
NET_RECEIVE(weight (microsiemens)) {
    a = a + weight*factor
    b = b + weight*factor
}
```

Example 10.5: use-dependent synaptic plasticity

Here the alpha function synapse is extended to implement a form of use-dependent synaptic plasticity. Each presynaptic event initiates two distinct processes: direct activation of ligand-gated channels, which causes a transient conductance change, and activation of a mechanism that in turn modulates the conductance change produced by successive synaptic activations. In this example we presume that modulation depends on the postsynaptic increase of a second messenger, which we will call "G protein" for illustrative purposes. We must point out that this example is entirely hypothetical, and

that it is quite different from models described by others [Destexhe, 1995 #168] in which the G protein itself gates the ionic channels.

For this mechanism it is essential to distinguish each stream into the generalized synapse, since each stream has to maintain its own [G] (concentration of activated G protein). That is, streams are independent of each other in terms of the effect on [G], but their effects on synaptic conductance show linear superposition.

Listing 10.4. gsyn.mod

The NET_RECEIVE block

The conductance of the ligand-gated ion channel uses the differential equation approximation for an alpha function synapse. The peak synaptic conductance depends on the value of [G] at the moment of synaptic activation. A similar, albeit much slower, alpha function approximation describes the time course of [G]. These processes peak approximately taul and Gtaul after delivery of an event, respectively.

The peak synaptic conductance elicited by an individual event is specified in the NET_RECEIVE block, where w = weight*(1+G2-G1) describes how the effective weight of the synapse is modified by [G]. Even though conductance is integrated, [G] is needed only at discrete event times so it can be computed analytically from the elapsed time since the prior synaptic activation. The INITIAL block sets up the factors that are needed to make the peak changes equal to the values of w and Ginc.

Note that G1 and G2 are not STATES in this mechanism. They are not even variables in this mechanism, but instead are "owned" by the particular NetCon instance that

delivered the event. Each NetCon object instance keeps an array (the weight vector) whose size equals the number of arguments to NET_RECEIVE, and the arguments to NET_RECEIVE are really references to the elements of this array. Unlike the arguments to a PROCEDURE or FUNCTION block, which are "call by value," the arguments to a NET_RECEIVE block are "call by reference." Therefore assignment statements in gsyn.mod's NET_RECEIVE block can change the

On initialization, all elements of the weight vector other than the first one are automatically set to 0. However, a NET_RECEIVE block may have its own INITIAL block, and this can contain statements that assign nonzero values to NetCon "states." Such an INITIAL block is executed when finitialize() is called.

values of variables that belong to the NetCon object, and this means that the NetCon's weight vector can be used to hold stream-specific state information. In the context of this particular example, each connection has its own [G], so gsyn uses "stream-specific plasticity" to represent "synapse-specific plasticity."

Figure 10.9. Simulation results from the model shown in Fig. 10.6 when the synaptic mechanism is GSyn. Note stream-specific use-dependent plasticity.

To illustrate the operation of this mechanism, imagine the network of Fig. 10.6 with a single GSyn driven by the two spike trains shown in Fig. 10.9. This emulates two synapses that are electrotonically close to each other, but with separate pools of [G]. The train with spikes at 5 and 45 ms (S1) shows some potentiation of the second conductance transient, but the train that starts at 15 ms with a 200 Hz burst of three spikes displays a large initial potentiation that is even larger when tested after a 40 ms interval.

Example 10.6: saturating synapses

Several authors (e.g. [Destexhe, 1994 #267], [Lytton, 1996 #206]) have used synaptic transmission mechanisms based on a simple conceptual model of transmitter-receptor interaction:

$$C + T \stackrel{\alpha}{\underset{\beta}{\leftarrow}} O \qquad \qquad \text{Eq. 10.2}$$

where transmitter *T* binds to a closed receptor channel *C* to produce an open channel *O*. In this conceptual model, spike-triggered transmitter release produces a transmitter concentration in the synaptic cleft that is approximated by a rectangular pulse with a fixed duration and magnitude (Fig. 10.10). A "large excess of transmitter" is assumed, so that while transmitter is present (the "onset" state, "ligand binding to channel") the postsynaptic conductance increases toward a maximum value with a single time constant $1/(\alpha T + \beta)$. After the end of the transmitter pulse (the "offset" state, "ligand channel complex dissociating"), the conductance decays with time constant $1/\beta$. Further details of saturating mechanisms are covered by [Destexhe, 1994 #267][Destexhe, 1994 #266] and [Lytton, 1996 #206].

Figure 10.10. A saturating synapse model. A single presynaptic spike (top trace) causes a pulse of transmitter in the synaptic cleft with fixed duration (Cdur) and concentration (middle trace). This elicits a rapid increase of postsynaptic conductance followed by a slower decay (bottom trace). A high frequency burst of spikes produces a sustained elevation of transmitter that persists until Cdur after the last spike and causes saturation of the postsynaptic conductance.

There is an ambiguity when one or more spikes arrive on a single stream during the onset state triggered by an earlier spike: should the mechanism ignore the "extra" spikes, concatenate onset states to make the transmitter pulse longer without increasing its concentration, or increase (summate) the transmitter concentration? Summation of transmitter requires the onset time constant to vary with transmitter concentration. This places transmitter summation outside the scope of the Destexhe/Lytton model, which assumes a fixed time constant for the onset state. We resolve this ambiguity by choosing concatenation, so that repetitive impulses on one stream produce a saturating conductance change (Fig. 10.10). However, conductance changes elicited by separate streams will summate.

A model of the form used in Examples 10.4 and 10.5 can capture the idea of saturation, but the separate onset/offset formulation requires keeping track of how much "material" is in the onset or offset state. The mechanism in Listing 10.5 implements an effective strategy for doing this. A noteworthy feature of this model is that the event delivery system serves as more than a conduit for receiving inputs from other cells: discrete events are used to govern the duration of synaptic activation, and are thus an integral part of the mechanism itself.

Listing 10.5. ampa.mod

The parameter block

The actual value of the transmitter concentration in the synaptic cleft during the onset state is unimportant to this model, as long as it remains constant. To simplify the mechanism, we assume transmitter concentration to be dimensionless, with a numeric value of 1. This allows us to specify the forward rate constant Alpha in units of 1/ms.

The STATE block

This mechanism has two STATES. Ron is the total conductance of all synapses that are in the onset state, and Roff is the total conductance of all synapses that are in the offset state. These are declared without units, so a units factor will have to be applied elsewhere (in this example, this is done in the BREAKPOINT block).

The INITIAL block

At the start of a simulation, we assume that all channels are closed and no transmitter is present at any synapse. The initial values of Ron, Roff, and synon must therefore be 0. This initialization happens automatically for STATES and does not require explicit specification in the INITIAL block, but synon needs an assignment statement. The INITIAL block also calculates Rtau and Rinf. Rtau is the time constant for equilibration of the closed (free) and open (ligand-bound) forms of the postsynaptic receptors when transmitter is present in the synaptic cleft. Rinf is the open channel fraction if transmitter is present forever.

The BREAKPOINT and DERIVATIVE blocks

The total conductance is numerically equal to Ron+Roff. The *1(umho) factor is included for dimensional consistency.

The DERIVATIVE block specifies the first order differential equations that govern these STATES. The meaning of each term in

Roff' = -Beta*Roff

is obvious, and in

Ron' = (synon*Rinf - Ron)/Rtau

the product synon*Rinf is the value that Ron approaches with increasing time.

The NET_RECEIVE block

The NET_RECEIVE block performs the task of switching each synapse between its onset and offset states. In broad outline, if an external event (an event generated by the NetCon's source passing threshold) arrives at time t to start an onset, the NET_RECEIVE block generates an event that it sends to itself. This self-event will be delivered at time

t+Cdur, where Cdur is the duration of the transmitter pulse. Arrival of the self-event is the signal to switch the synapse back to the offset state. If another external event arrives from the same NetCon before the selfevent does, the self-event is moved to a new time that is Cdur in the future. Thus resetting to the offset state

"External event" and "input event" are synonyms. We will use the former term as clarity dictates when contrasting them with self-events.

can happen only if an interval of Cdur passes without new external events arriving.

To accomplish this strategy, the NET_RECEIVE block must distinguish an external

event from a self-event. It does this by exploiting the fact that every event has an implicit argument called flag, the value of which is automatically 0 for an external event.

The event flag is "call by value," unlike the explicit arguments that are declared inside the parentheses of the NET_RECEIVE() statement, which are "call by reference."

Handling of external events

Arrival of an external event causes execution of the statements inside the if (flag==0) {} clause. These begin with if (!on), which tests whether this synapse should switch to the onset state.

Switching to the onset state involves keeping track of how much "material" is in the onset and offset states. This requires moving the synapse's channels into the pool of channels that are exposed to transmitter, which simply means adding the synapse's weight to synon. Also, the conductance of this synapse, which had been decaying with rate constant 1/Beta, must now start to grow with rate constant Rtau. This is done by

computing r0, the synaptic conductance at the present time t, and then adding r0 to Ron and subtracting it from Roff. Next the value of t0 is updated for future use, and on is set to 1 to signify that the synapse is in the onset state. The last statement inside if (!on){} is net_send(Cdur,nspike), which generates a self-event with delay given by the first argument and flag value given by the second argument. All the explicit arguments of this self-event will have the values of this particular NetCon, so when this self-event returns we will know how much "material" to switch from the onset to the offset state.

The else {} clause takes care of what happens if another external event arrives while the synapse is still in the onset state. The net_move(t+Cdur) statement moves the self-event to a new time that is Cdur in the future (relative to the arrival time of the new external event). In other words, this prolongs synaptic activation until Cdur after the most recent external event.

Handling of self-events

When the self-event is finally delivered, it triggers an offset. We know it is a selfevent because its flag is 1. Once again we keep track of how much "material" is in the onset and offset states, but now we subtract the synapse's weight from synon to remove the synapse's channels from the pool of channels that are exposed to transmitter. Likewise, the conductance of this synapse, which was growing with rate constant Rtau, must now begin to decay with rate constant 1/Beta. Finally, the value of t0 is updated and on is reset to 0.

Artificial spiking cells

NEURON's event delivery system was created with the primary aim of making it easier to represent synaptic connections between biophysical model neurons. However, the event delivery system turns out to be quite useful for implementing a wide range of mechanisms that require actions to be taken after a delay. The saturating synapse model presented above is just one example of this.

The previous section also showed how spike-triggered synaptic transmission makes extensive use of the network connection class to define connections between cells. The typical NetCon object watches a source cell for the occurrence of a spike, and then, after some delay, delivers a weighted event to a target synaptic mechanism, i.e. it is a metaphor for axonal spike propagation. More generally, a NetCon object can be regarded as a channel on which a stream of events generated at a source is transmitted to a target. The target can be a point process, a distributed mechanism, or an artificial neuron (e.g. an integrate and fire model). The effect of events on a target is specified in NMODL by statements in a NET_RECEIVE block, which is called only when an event has been delivered.

The event delivery system also opens up a large domain of simulations in which certain types of artificial spiking cells, and networks of them, can be simulated hundreds of times faster than with numerical integration methods. Discrete event simulation is possible when all the state variables of a model cell can be computed analytically from a new set of initial conditions. That is, if an event occurs at time t_1 , all state variables must be computable from the state values and time t_0 of the previous event. Since computations are performed only when an event occurs, total computation time is proportional to the number of events delivered and independent of the number of cells, number of connections, or problem time. Thus handling 100,000 spikes in one hour for 100 cells takes the same time as handling 100,000 spikes in 1 second for 1 cell.

Artificial spiking cells are implemented in NEURON as point processes, but unlike ordinary point processes, they can serve as targets and sources for NetCon objects. They can be targets because they have a NET_RECEIVE block, which specifies how incoming events from one or more NetCon objects are handled, and details the calculations necessary to generate outgoing events. They can also be sources because the same NET_RECEIVE block generates discrete output events which are delivered through one or more NetCon objects to targets.

The following examples analyze the three broad classes of integrate and fire cells that are built into NEURON. In order to emphasize how the event delivery system is used to implement the dynamics of these mechanisms, we have omitted many details from the NMODL listings. Ellipses indicate elisions, and listings include *italicized pseudocode* where necessary for clarity. Complete source code for all three of these cell classes is provided with NEURON.

Example 10.7: IntFire1, a basic integrate and fire model

The simplest integrate and fire mechanism built into NEURON is IntFire1, which has a membrane state variable m (analogous to membrane potential) which decays toward 0 with time constant τ .

$$\tau \ \frac{dm}{dt} + m = 0$$
 Eq. 10.3

An input event of weight w adds instantaneously to m, and if m reaches or exceeds the threshold value of 1, the cell "fires," producing an output event and returning m to 0. Negative weights are inhibitory while positive weights are excitatory. This is analogous to a cell with a membrane time constant τ that is very long compared to the time course of individual synaptic conductance changes. Every synaptic input to such a cell shifts membrane potential to a new level in a time that is much shorter than τ , and each cell firing erases all traces of prior inputs. Listing 10.6 presents an initial implementation of IntFire1.

```
NEURON {
    ARTIFICIAL_CELL IntFire1
    RANGE tau, m
}
PARAMETER { tau = 10 (ms) }
```

```
ASSIGNED {
  m
  t0 (ms)
}
INITIAL {
  m = 0
  t0 = 0
}
NET_RECEIVE (w) {
  m = m^* \exp(-(t - t0)/tau)
  m = m + w
  t0 = t
  if (m > 1) {
    net event(t)
    m = 0
  }
}
```

Listing 10.6. A basic implementation of IntFire1.

The NEURON block

As the introduction to this section mentions, artificial spiking cells are implemented in NEURON as point processes. The keyword ARTIFICIAL_CELL is in fact a synonym for POINT_PROCESS, but we use it as a deliberate reminder that this model has a NET_RECEIVE block, lacks a BREAKPOINT block, and does not have to be associated with a section location or numerical integrator. Unlike other point processes, an artificial cell is isolated from the usual things that link mechanisms to each other: it does not refer to membrane potential v or any ions, and it does not use POINTER variables. Instead, the "outside" can affect it only by sending it discrete events, and it can only affect the "outside" by sending discrete events.

The NET_RECEIVE block

The mechanisms we have seen so far use BREAKPOINT and KINETIC or DERIVATIVE blocks to specify the calculations that are performed during a time step dt, but an artificial cell model does not have these blocks. Instead, calculations only take place when a new event arrives, and these are performed in the NET_RECEIVE block.

When a NetCon delivers a new event to an IntFire1 cell, the present value of m is computed analytically and then m is incremented by the weight w of the event. According to the NET_RECEIVE block, the present value of m is found by applying an exponential decay to the value it had immediately after the previous event; therefore the code contains variable t0 which keeps track of the last event time.

If an input event drives m to or above threshold, the net_event(t) statement notifies all NetCons, for which this point process is the source, that it fired a spike at time t (the argument to net_event() can be any time at or later than the current time t). Then the cell resets m to 0. The code in Listing 10.6 imposes no limit on firing frequency--if a NetCon with delay of 0 and a weight of 1.1 has such an artificial cell as both its source and target, the system will behave "properly," in the sense that events will be generated and delivered without time ever advancing. It is easy to prevent the occurrence of such a runaway stream of events (see *Adding a refractory period* below).

There is no threshold test overhead at every dt because IntFirel has no variable for NetCons to watch. That is, this artificial spiking cell does not need the usual test for local membrane potential v to cross NetCon.threshold, which is essential at every time step for event generation with biophysical neuron models. Furthermore the event delivery system only places the earliest event to be delivered on the event queue. When that time finally arrives, all targets whose NetCons have the same source and delay get the event delivery, and longer delay streams are put back on the event queue to await their specific delivery time.

Enhancements to the basic mechanism

Visualizing the membrane state variable

The membrane state variable m is difficult to plot in an understandable manner, since it is represented in the computer by a variable m that remains unchanged over the interval between input events regardless of how many numerical integration steps were performed in that interval. Consequently m always has the value that was calculated after the last event was received, and plots of it look like a staircase (Fig. 10.11 left), with no apparent decay or indication of what the value of m was just before the event.

Figure 10.11. Response of an IntFirel cell with $\tau = 10$ ms to input events with weight = 0.8 arriving at t = 5, 22, and 25 ms (arrows). The third input initiates a "spike." Left: The variable m is evaluated only when a new event arrives, so its plot looks like a staircase. A function can be included in IntFirel's mod file (see text) to better indicate the time course of the membrane state variable *m*. Center: Plotting this function during a simulation with fixed dt (0.025 ms here) demonstrates the decay of *m* between events. Right: In a variable time step simulation, *m* appears to follow a sequence of linear ramps. This artifact is a consequence of the efficiency of adaptive integration, which computed analytical solutions at only a few instants, so the Graph tool could only draw lines from instant to instant.

This can be partially repaired by adding a function

```
FUNCTION M() {
    M = m*exp(-(t - t0)/tau)
}
```

that returns the present value of the membrane state variable *m*. This gives nice trajectories when fixed time step integration is used (Fig. 10.11 center). However, the natural step with the variable step method is the interspike interval itself, unless intervening events occur in other cells (e.g. 1 ms before the second input event in Fig. 10.11 right). At least the integration step function fadvance() returns 10^{-9} ms before and after the event to properly indicate the discontinuity in M.

Adding a refractory period

It is easy to add a relative refractory period by initializing m to a negative value after the cell fires (alternatively, a depolarizing afterpotential can be emulated by initializing mto a value in the range (0,1)). However, incorporating an absolute refractory period requires self-events.

Suppose we want to limit the maximum firing rate to 200 spikes per second, which corresponds to an absolute refractory period of 5 ms. To specify the duration of the refractory period, we use a variable named refrac, which is declared and assigned a value of 5 ms in the PARAMETER block. Adding the statement RANGE refrac to the NEURON block allows us to adjust this parameter from the interpreter and graphical interface. We also use a variable to keep track of whether the point process is in the refractory period or not. The name we choose for this variable is the eponymous refractory, and it is declared in the ASSIGNED block and initialized to a value of 0 ("false") in the INITIAL block.

The NET_RECEIVE implementation is then

```
NET_RECEIVE (w) {
  if (refractory == 0) {
    m = m \exp(-(t - t0)/tau)
    m = m + w
    t0 = t
    if (m > 1) {
      net_event(t)
      refractory = 1
      net_send(refrac, refractory)
  } else if (flag == 1) {
    : self-event arrived, so terminate refractory period
    refractory = 0
    m = 0
    t0 = t
  }
    : else ignore the external event
}
```

If refractory equals 0, the cell accepts external events (i.e. events delivered by a NetCon) and calculates the state variable m and whether to fire the cell. When the cell fires a spike, refractory is set to 1 and further external events are ignored until the end of the refractory period (Fig. 10.12).

Recall from the saturating synapse example that the flag variable that accompanies an external event is 0. If this mechanism receives an event with a nonzero flag, it must be a self-event, i.e. an event generated by acall to net_send() when the cell fired. The net_send(interval, flag) statement places an event into the delivery system as an "echo" of the current event, i.e. it will come back to the sender after the specified interval with the specified flag. In this case we aren't interested in the weight but only the flag. Arrival of this self-event means that the refractory period is over.

The top of Fig. 10.12 shows the response of this model to a train of input stimuli. Temporal summation triggers a spike on the fourth input. The fifth input arrives during the refractory interval and has no effect.

Figure 10.12. Response of an IntFire1 cell with a 5 ms refractory interval to a run of inputs at 3 ms intervals (arrows), each with weight = 0.4. Top: The cell accepts inputs when refractory == 0. The fourth input (at 11 ms) drives the cell above threshold. This triggers an output event, increases refractory to 1 (top trace), and function M, which reflects the membrane state variable *m*, jumps to 2. During the 5 ms refractory period, M decays gradually, but the cell is unresponsive to further inputs (note that the input at 14 ms produces no change in the membrane state variable). At 16 ms refractory falls to 0, making the cell once again responsive to inputs, and M also returns to 0 until the next external event arrives. Bottom: After modifying the function M to generate rectangular pulses that emulate a spike followed by postspike hyperpolarization.

Improved presentation of the membrane state variable

The performance in the top of Fig. 10.12 is satisfactory, but the model could be further improved by one relatively minor change. As it stands the M function shows an exponential decay during the refractory period, which is at best distracting and irrelevant to the operation of the model, and potentially misleading at worst. It would be better for M to follow a stereotyped time course, e.g. a brief positive pulse followed by a longer

negative pulse. This would not be confused with the subthreshold operation of the model, and it might be more suggestive of an action potential.

The most direct way to do this is to make M take different actions depending on whether or not the model is "spiking." One possibility is

```
FUNCTION M() {
    if (refractory == 0) {
        M = m*exp(-(t - t0)/tau)
    } else if (refractory == 1) {
        if (t - t0 < 0.5) {
            M = 2
        } else {
            M = -1
        }
    }
}</pre>
```

which is exactly what the built-in IntFire1 model does. The bottom of Fig. 10.12 shows the time course of this revised function.

This demonstrates how visualization of cell operation can be enhanced by simple calculations of patterns for the spiking and refractory trajectories, with no overhead for cells that are not plotted. We must emphasize that the simulation calculations are analytic and performed only at event arrival, regardless of the refinements we introduced for the purpose of esthetics.

Sending an event to oneself to trigger deferred computation involves very little overhead, yet it allows elaborate calculations to be performed much more efficiently than if they were executed on a per dt basis. Self-events are heavily exploited in the implementation of IntFire2 and IntFire4, which both offer greater kinetic complexity than IntFire1.

Example 10.8: IntFire2, firing rate proportional to input

The IntFire2 model, like IntFire1, has a membrane state variable *m* that follows first order kinetics with time constant τ_m . However, an input event to IntFire2 does not affect *m* directly. Instead it produces a discontinuous change in a synaptic current state variable *i*. Between events, *i* decays with its own time constant τ_s toward a steady "bias" value specified by the parameter i_b . That is,

$$\tau_s \frac{di}{dt} + i = i_b$$
 Eq. 10.4

where an input event causes i to change abruptly by w (Fig. 10.13 top). This current i drives m, i.e.

$$\tau_m \, \frac{dm}{dt} + m = i \qquad \qquad \text{Eq. 10.5}$$

where $\tau_m < \tau_s$. Thus an input event produces a gradual change in *m* that is described by two time constants and approximates an alpha function if $\tau_m \approx \tau_s$. When *m* crosses a threshold of 1 in a positive direction, the cell fires, *m* is reset to 0, and integration resumes immediately, as shown in the bottom of Fig. 10.13. Note that *i* is not reset to 0, i.e. unlike IntFire1, firing of an IntFire2 cell does not obliterate all traces of prior synaptic activation.

Figure 10.13. Top: Time course of synaptic current *i* in an IntFire2 cell with $\tau_s = 20$ ms and $\tau_m = 10$ ms. This cell has bias current $i_b = 0.2$ and receives inputs with weight w = 1.4 at t = 50 and 100 ms. Bottom: The membrane state variable *m* of this cell is initially 0 and approaches the value of i_b (0.2 in this example) with time constant τ_m . The first synaptic input produces a subthreshold response, but temporal summation drives *m* above threshold at t = 109.94 ms. This resets *m* to 0 and integration resumes.

Depending on its parameters, IntFire2 can emulate a wide range of relationships between input pattern and firing rate. Its firing rate is ~ i / τ_m if i is >> 1 and changes slowly compared to τ_m .

The parameter i_b is analogous to the combined effect of a baseline level of synaptic drive plus a bias current injected through an electrode. The requirement that $\tau_m < \tau_s$ is equivalent to asserting that the membrane time constant is faster than the decay of the current produced by an individual synaptic activation. This is plausible for slow inhibitory inputs, but where fast excitatory inputs are concerned an alternative interpretation can be applied: each input event signals an abrupt increase (followed by an exponential decline) in the mean firing rate of one or more afferents that produce brief but temporally overlapping postsynaptic currents. The resulting change of *i* is the moving average of these currents.

The IntFire2 mechanism is amenable to discrete event simulation because Eqns. 10.4 and 10.5 have analytic solutions. If the last input event was at time t_0 and the values of *i* and *m* immediately after that event were $i(t_0)$ and $m(t_0)$, then their subsequent time course is given by

$$i(t) = i_b + [i(t_0) - i_b] e^{-(t - t_0)/\tau_s}$$
 Eq. 10.6

and

$$m(t) = i_{b} + \left[i(t_{0}) - i_{b}\right] \frac{\tau_{s}}{\tau_{s} - \tau_{m}} e^{-(t - t_{0})/\tau_{s}} + \left[m(t_{0}) - i_{b} - \left[i(t_{0}) - i_{b}\right] \frac{\tau_{s}}{\tau_{s} - \tau_{m}}\right] e^{-(t - t_{0})/\tau_{m}}$$
Eq. 10.7

Implementation in NMODL

The core of the NMODL implementation of IntFire2 is the function firetime(), which is discussed below. This function projects when m will equal 1 based on the present values of i_b , i, and m, assuming that *no new input events arrive*. The value

returned by firetime() is 10^9 if the cell will never fire with no additional input. Note that if $i_b > 1$ the cell fires spontaneously even if no input events occur.

```
INITIAL {
  net_send(firetime(args), 1)
}
NET_RECEIVE (w) {
  if (flag == 1) { : time to fire
   net_event(t)
    m = 0
    net_send(firetime(args), 1)
  } else {
    update m
    if (m >= 1) {
      net_move(t) : the time to fire is now
    } else {
      net_move(firetime(args) + t)
    }
  }
  update t0 and i
}
```

Listing 10.7. Key excerpts from intfire2.mod

The INITIAL block in IntFire2 calls firetime() and uses the returned value to put a self-event into the delivery system. The strategy, which is spelled out in the NET_RECEIVE block, is to respond to external events by moving the delivery time of the self-event back and forth with the net_move() function. When the self-event is finally delivered (potentially never), net_event() is called to signal that this cell is firing. Notice that external events always have an effect on the value of *i*, and are never ignored--and shouldn't be, even if we introduced a refractory period in which we refused to integrate *m*.

The function first $t \ge 0$ for which

$$a + b e^{-t/\tau_s} + (c - a - b) e^{-t/\tau_m} = 1$$
 Eq. 10.8

where the parameters *a*, *b* and *c* are defined by the coefficients in Eq. 10.7. If there is no such *t* the function returns 10^9 . This represents the time of the next cell firing, relative to the time t_0 of the most recent synaptic event.

Since firetime() must be executed on every input event, it is important to minimize the number of Newton iterations needed to calculate the next firing time. For this we use a strategy that depends on the behavior of the function

$$f_1(x) = a + b x^r + (c - a - b) x$$
 Eq. 10.9a

where
$$x = e^{-t/\tau_m}$$

 $r = \tau_m/\tau_s$
Eq. 10.9b

over the domain $0 < x \le 1$. Note that c < 1 is the value of f_1 at x = 0 (i.e. at $t = \infty$). The function f_1 is either linear in x (if b = 0) or convex up (b > 0) or down (b < 0) with no inflection points. Since r < 1, f_1 is tangent to the y axis for any nonzero b (i.e. f_1 (0) is infinite).

Figure 10.14. Plots of f_1 and f_2 computed for r = 0.5. See text for details.

The left panel of Fig. 10.14 illustrates the qualitative behavior of f_1 for $a \le 1$. It is easy to analytically compute the maximum in order to determine if there is a solution to $f_1(x) = 1$. If a solution exists, f_1 will be concave downward so Newton iterations starting at x = 1 will underestimate the firing time.

For a > 1, a solution is guaranteed (Fig. 10.14 middle). However, starting Newton iterations at x = 1 is inappropriate if the slope there is more negative than c - 1 (straight dashed line in Fig. 10.14 middle). In that case, the transformation $x = e^{-t/\tau_s}$ is used, giving the function

$$f_2(x) = a + b x + (c - a - b) x^{1/r}$$
 Eq. 10.9c

and the Newton iterations begin at x = 0 (Fig. 10.14 right).

These computations are performed over regions in which f_1 and f_2 are relatively linear, so the firetime() function usually requires only two or three Newton iterations to converge to the next firing time. The only exception is when f_1 has a maximum that is just slightly larger than 1, in which case it may be a good idea to stop after a couple of iterations and issue a self-event. The advantage of this would be the deferral of a costly series of iterations, allowing an interval in which another external event might arrive that would force computation of a new projected firing time. Such an event, whether excitatory or inhibitory, would likely make it easier to compute the next firing time.

Example 10.9: IntFire4, different synaptic time constants

IntFire2 can emulate an input-output relationship with more complex dynamics than IntFire1 does, but it is somewhat restricted because its response to every external event, whether excitatory or inhibitory, has the same kinetics. As we pointed out in the discussion of IntFire2, it is possible to interpret excitatory events in a way that partially sidesteps this issue. However, experimentally observed synaptic excitation tends to be faster than inhibition (e.g. [Destexhe, 1998 #278]) so a more flexible integrate and fire mechanism is needed.

The IntFire4 mechanism addresses this need. Its dynamics are specified by four time constants: τ_e for a fast excitatory current, τ_{i_1} and τ_{i_2} for a slower inhibitory current, and τ_m for the even slower leaky "membrane" which integrates these currents. When the membrane state variable *m* reaches 1, the cell "fires," producing an output event and returning *m* to 0. This does not affect the other states of the model.

The differential equations that govern IntFire4 are

$$\frac{de}{dt} = -k_e e Eq. 10.10$$

$$\frac{di_1}{dt} = -k_{i_1}i_1$$
 Eq. 10.11

$$\frac{di_2}{dt} = -k_{i_2}i_2 + a_{i_1}i_1$$
 Eq. 10.12

$$\frac{dm}{dt} = -k_m m + a_e e + a_{i_2} i_2$$
 Eq. 10.13

where each *k* is a rate constant that equals the reciprocal of the corresponding time constant, and it is assumed that $k_e > k_{i_1} > k_{i_2} > k_m$ (i.e. $\tau_e < \tau_{i_1} < \tau_{i_2} < \tau_m$). An input event with weight w > 0 (i.e. an excitatory event) adds instantaneously to the excitatory current *e*. Equations 10.11 and 12, which define the inhibitory current i_2 , are based on the reaction scheme

$$\begin{array}{c} k_{i_1} & k_{i_2} \\ i_1 \rightarrow i_2 \rightarrow bath \end{array}$$
 Eq. 10.14

in which an input event with weight w < 0 (i.e. an inhibitory event) adds instantaneously to i_1 . The constants a_e , a_{i_1} , and a_{i_2} are chosen to normalize the response of the states e, i_1 , i_2 , and m to input events (Fig. 10.15). Therefore an input with weight $w_e > 0$ (an "excitatory" input) produces a peak e of w_e and a maximum "membrane potential" m of w_e . Likewise, an input with weight $w_i < 0$ (an "inhibitory" input) produces an inhibitory current i_2 with a minimum of w_i and drives m to a minimum of w_i . Details of the analytic solution to these equations are presented in **Appendix A1: Mathematical analysis of** IntFire4.

Figure 10.15. Left: Current generated by a single input event with weight 0.5 (*e*) or -0.5 (*i*₂). Right: The corresponding response of *m*. Parameters were $\tau_e = 3$, $\tau_{i_1} = 5$, $\tau_{i_2} = 10$, and $\tau_m = 30$ ms.

IntFire4, like IntFire2, finds the next firing time through successive approximation. However, IntFire2 generally iterates to convergence every time an input event is received, whereas IntFire4's algorithm implement a series of deferred Newton iterations by exploiting the downward convexity of the membrane potential trajectory and using NEURON's event delivery system. The result is an alternating sequence of self-events and single Newton iterations that converges to the correct firing time, yet remains computationally efficient in the face of heavy input event traffic.

This is illustrated in Fig. 10.16. If an event arrives at time t_0 , values of $e(t_0)$, $i_1(t_0)$, $i_2(t_0)$, and $m(t_0)$ are calculated analytically. Should $m(t_0)$ be subthreshold, the self-event is moved to a new approximate firing time t_f that is based on the slope approximation to m

$$t_f = t_0 + (1 - m(t_0)) / m'(t_0)$$
 if $m'(t_0) > 0$ Eq. 10.15
or
 ∞ if $m'(t_0) \le 0$

(Fig. 10.16 left and middle). If instead $m(t_0)$ reaches threshold, the cell "fires" so that net_event() is called (producing an output event that is picked up by all NetCons for which this cell is a source) and m is reset to 0. The self-event is then moved to an approximate firing time that is computed from Eq. 10.15 using the values assigned to m and m immediately after the "spike" (Fig. 10.16 right).

Figure 10.16. Excerpts from simulations of IntFire4 cells showing time course of *m*. Arrival of an event (arrow = external event, vertical dotted line = self-event) triggers a Newton iteration. Slanted dashed lines are slope approximations to *m* immediately after an event. Left: Although Eq. 10.15 yields a finite t_f , this input is too weak for the cell to fire. Middle: Here m' < 0 immediately after an input event, so both t_f and the true firing time are infinite. Right: The slope approximation following the excitatory input is not shown, but it obviously crosses threshold before the actual firing time (asterisk). Following the "spike" *m* is reset to 0 but bounces back up because of persistent excitatory current. This dies away without eliciting a second spike, even though t_f is finite (dashed line).

Figure 10.17. These magnified views of the trajectory from the right panel of Fig. 10.16 indicate how rapidly the event-driven Newton iterations converge to the next firing time. In this simulation, spike threshold was reached in four iterations after the excitatory input (arrow). The first two iterations are evident in the left panel, and additional magnification of the circled region reveals the last two iterations (right panel).

The justification for this approach stems from several considerations. The first of these is that t_f is never later than the true firing time. This assertion, which we prove in **Appendix A1**, is of central importance because the simulation would otherwise be in error.

Another consideration is that successive approximations must converge rapidly to the true firing time, in order to avoid the overhead of a large number of self-events. Using the slope approximation to m is equivalent to the Newton method for solving m(t) = 1, so convergence is slow only when the maximum value of m is close to 1. The code in IntFire4 guards against missing "real" firings when m is asymptotic to 1, because it actually tests for m > 1 - eps, where the default value of eps is 10^{-6} . This convergence tolerance eps is a user-settable GLOBAL parameter, so one can easily augment or override this protection.

Finally, the use of a series of self-events is superior to carrying out a complete Newton method solution because it is most likely that external events will arrive in the interval between firing times. Each external event would invalidate the previous computation of firing time and force a recalculation. This might be acceptable for the IntFire2 mechanism with its efficient convergence, but the complicated dynamics of IntFire4 suggest that the cost would be too high. How many iterations should be carried out per self-event is an experimental question, since the self-event overhead depends partly on the number of outstanding events in the event queue.

Other comments regarding artificial spiking cells

NEURON's event delivery system has been used to create many more kinds of artificial spiking neurons than the three classes that we have just examined. Specific examples include pacemakers, bursting cells, models with various forms of use-dependent synaptic plasticity, continuous or quantal stochastic variation of synaptic weight, and an "IntFire3" with a bias current and time constants $\tau_m > \tau_i > \tau_e$.
