Yale University, New Haven, CT, USA

Network modeling is a common research activity in computational neuroscience. As a general rule, investigators eventually find that they need to study larger and more complex models. Often this runs up against storage and runtime limitations that interfere with achieving their goals. An obvious solution is to move to parallel simulations which accommodates larger networks on hardware with multiple processors and large amounts of total memory.

Migliore et al. (Migliore et al. 2006) showed that large gains can be achieved with NEURON by distributing network models over multiple processors. They introduced the framework used in NEURON for parallel simulations, and examined performance scaling with published models. They found linear improvement of execution speed until there were so many processors, each working on such a small task, that communication became rate limiting (about 100 ODEs per processor).

Investigators increasingly have ready access to parallel hardware, such as multiprocessor personal computers, workstation clusters, and massively parallel supercomputers. The practical question is how to move a working network model from a single processor to parallel hardware. The aim of this paper is to show how to make this transition for a model implemented with NEURON. This is written from the perspective of UNIX/Linux, but the basic concepts are independent of the operating system, as are all NEURON programming issues.

NEURON offers users the ability to parallelize network models while maintaining, as much as possible, a separation between the specification of the network (i.e. all of the cells and all of the connections between them), and how the cells are distributed among the host CPUs. This makes it possible to write code that will execute properly, without modification, in any serial or parallel hardware environment, producing quantitatively identical results regardless of the number of CPUs or which CPU handles which cell(s). In this document we present two concrete examples of how this is done.

2. Materials and Methods

The literature on parallel processing is full of "terms of art," such as CPUs, cores, processors, processing units, nodes, and hosts, but unfortunately these are not used synonymously by everyone. Here we define the number of *processing units* in a computer to be the number of programs that can be executed simultaneously. For the sake of convenience, we refer to each processing unit as a *processor*, so what is commonly called a "dual core, dual processor" PC has four processing units, or four processors. When a processor is part of a parallel computing architecture, it is called a *host*. Note that the latter differs from the usage of host in discussions of computer networking, where it refers to an individual server or workstation.

2.1 Installation and configuration of software

2.1.1 Installing and testing MPI

For parallel simulations, installation of NEURON requires a pre-existing installation of MPI-1.1 (Message Passing Interface) standard or greater. MPI almost certainly exists on any parallel hardware that accepts remote login clients. The easiest way to find out if MPI has already been installed is to ask your system administrator. Otherwise, with a UNIX command line

```
which mpicc
which mpic++ # or mpicxx, mpiCC, ...
```

will at least tell if it is in your PATH.

Individuals who have multiprocessor workstations, or who wish to configure their own private workstation cluster, have a variety of choices of open source implementation of the MPI standard. For example one can obtain MPICH2 from http://www-unix.mcs.anl.gov/mpi/mpich2/.

Unfortunately, the syntax for launching a program is different for every implementation of MPI, and also depends on the nature of the parallel hardware, i.e. supercomputer, workstation

cluster, or standalone multiprocessor personal computer. Furthermore, the launch process itself is often encapsulated in batch queue control programs, e.g. LoadLeveler, PBS, etc.. Regardless of the details, the underlying principles are the same, but for the sake of illustration it is helpful to have a concrete example, so we will assume the simplest case: MPICH2 on a standalone multiprocessor personal computer.

With the proviso that versions and README instructions may change, this sequence of commands will download and install MPICH2

```
curl http://www-unix.mcs.anl.gov/mpi/mpich2/downloads\
     /mpich2-1.0.5p2.tar.gz > mpich2-1.0.5p2.tar.gz
tar xzf mpich2-1.0.5p2.tar.gz
cd mpich2-1.0.5p2
./configure --prefix=$HOME/mpich2
make
make install
export PATH=$HOME/mpich2/bin:$PATH
```

Setting up a cluster that has several hosts will also probably involve creating a file that lists those hosts. Also, before testing on a workstation cluster that has a shared file system, make sure that you can login to any node using ssh without a password, e.g. `ssh `hostname``. If not,

```
ssh-keygen -t rsa
cd $HOME/.ssh; cat id_rsa.pub >> authorized_keys
```

It may also be necessary to explicitly set permissions on the `authorized_keys` file

```
chmod 600 .ssh/authorized_keys
```

Of course, proper functioning of the installed software should be verified. You must be able to start, query, and stop the MPI daemon

```
$ mpdboot
$ mpdtrace
localhost
$ mpdallexit
```

(listings that combine user entries and computer responses use $ to denote the system prompt, display user entries in **bold monospace**, and show computer responses as `plain monospace`). In addition, it is a good idea to build and run one or more of the test programs that are distributed with MPICH2, such as `cpi_anim`.

```
$ cd $HOME/mpich2/share/examples_graphics
$ make
$ mpiexec -np 4 cpi_anim
Process 0 on localhost.localdomain
Process 2 on localhost.localdomain
```

```
Process 3 on localhost.localdomain
Process 1 on localhost.localdomain
pi is approximately 3.1416009869231249, Error is 0.0000083333333318
wall clock time = 0.041665
```

Observe that the `-np 4` argument caused four processes to be launched. Ordinarily, the chosen number of processes will match the number of processing units. However, to check that things are working properly, it is very useful to test with a single process (`-np 1`). If the processes have a very wide range of run times, it may be useful to launch many more processes than there are processing units, thereby letting the operating system balance the problem.

2.1.2 Building and testing NEURON

This sequence of commands will download and install NEURON 6.0 and InterViews 17:

```
mkdir $HOME/neuron
cd $HOME/neuron
# download and install InterViews
# unnecessary if you will only run in batch mode
curl http://www.neuron.yale.edu/ftp/neuron/versions\
      /v6.0/iv-17.tar.gz | tar xzf
cd iv-17
./configure --prefix=`pwd`
make
make install
cd ..
# download and install NEURON
curl http://www.neuron.yale.edu/ftp/neuron/versions\
      /v6.0/nrn-6.0.tar.gz |tar xzf
cd nrn-6.0
# if InterViews is not installed, replace "--with-iv..." with
# --without-x
./configure --prefix=`pwd` --with-iv=$HOME/neuron/iv-17 \
      --with-paranrn
make
make install
export CPU=i686 # or perhaps x86_64--to decide which you have,
               # list the directory, or run ./config.guess
export PATH=$HOME/neuron/iv-17/$CPU/bin:$HOME/neuron\
      /nrn-6.0/$CPU/bin:$PATH
```

NEURON is distributed with several test programs that are located in `nrn-x.x/src/parallel`, where `x.x` is the version number. The simplest is `test0.hoc`

```
objref pc
pc = new ParallelContext()
strdef s
```

```
{
system("hostname", s)
printf("There are %d processes. My rank is %d and I am on %s\n" \
      pc.nhost, pc.id, s)
}
{pc.runworker()}
{pc.done()}
quit()
```

`pc.nhost` is a synonym for the number of processes, i.e. the value of the `-np` argument. `pc.id` is a synonym for the MPI rank of a process, and ranges from 0 to `pc.nhost-1`. Running `test0.hoc` under MPI with `-np 4`

```
$ cd src/parallel
$ mpiexec -np 4 $HOME/neuron/nrn-6.0/$CPU/bin/nrniv -mpi test0.hoc
```

should generate this output on a "dual core, dual processor" PC

```
There are 4 processes. My rank is 0 and I am on localhost.localdomain
There are 4 processes. My rank is 1 and I am on localhost.localdomain
There are 4 processes. My rank is 2 and I am on localhost.localdomain
There are 4 processes. My rank is 3 and I am on localhost.localdomain
```

Note the `-mpi` switch in the command line, which tells NEURON that it is running in parallel mode, so that each process is assigned a different rank. Trying again but omitting `-mpi`

```
$ mpiexec -np 4 $HOME/neuron/nrn-6.0/$CPU/bin/nrniv test0.hoc
```

makes NEURON run in serial mode, so the four processes will execute one after another with no communication between them, and NEURON sets `pc.id` to 0 and `pc.nhost` to 1

```
There are 1 processes. My rank is 0 and I am on localhost.localdomain
There are 1 processes. My rank is 0 and I am on localhost.localdomain
There are 1 processes. My rank is 0 and I am on localhost.localdomain
There are 1 processes. My rank is 0 and I am on localhost.localdomain
```

One small but very practical issue deserves mention: NEURON has many commonly used procedures and methods that return a numerical result which is printed to standard output when they are executed at the top level of the interpreter, e.g. `load_file()`, `system()`, `pc.runworker()`. This may be helpful for development and debugging, but can be a big nuisance when a program runs in parallel mode on more than a few processors. Printing of dozens (or thousands) of lines of 0s and 1s can be suppressed by surrounding offending statements with pairs of curly brackets, as in

```
{pc.runworker()}
```

2.2 Important concepts

NEURON uses an event delivery system to implement spike-triggered synaptic transmission between cells ((Hines and Carnevale 2004), chapter 10 in (Carnevale and Hines 2006)). In the simplest case on serial hardware, the connection between a spike source (presynaptic cell) and its target is made by executing a statement of the form

```
nc = new NetCon(source, target)
```

This creates an object of the NetCon (**Net**work **Con**nection) class, which monitors a source (presynaptic cell) for spikes. Detection of a spike launches an event which, after an appropriate delay, will be delivered to the NetCon's target. The target is either an artificial spiking cell or a synaptic mechanism attached to a biophysical model cell (Fig. 2.2.1; also see Fig. 3.2). In either case, delivery of the event causes some change in the postsynaptic cell.
Figure 2.2.1. A NetCon attached to the presynaptic neuron PreCell detects spikes at the location labeled source, and delivers events to the synapse target which is attached to the postsynaptic neuron PostCell.

The basic problem that has to be overcome in a parallel simulation environment is that the source cell and its target usually do not exist on the same host. The solution is to give each cell (spike source) its own global identifier (*gid*) that can be referred to by every host. Then, if a presynaptic cell on one host generates a spike, a message that notes the gid and time of the spike will be passed to all other hosts. NetCons on those hosts that have this gid as their source will then deliver events to PreCell's targets with appropriate delays and weights (Fig. 2.2.2).

Synapses usually far outnumber spike sources, but fortunately synapse identifiers are unnecessary because we use a target-centric strategy to set up network connections. That is, each host is asked to execute the following conceptual task

```
for each cell c on this host {
    for each spike source gid s that targets c {
        set up a connection between spike source s and the proper target synapse on c
    }
}
```

Figure 2.2.2. A presynaptic spike source PreCell with gid = 7 is on host 2, but its target is a synapse attached to PostCell on host 4. If PreCell spikes, a message is passed to all hosts so that `NetCons` that have gid 7 as their source will deliver events to their targets.

3. First example: a ring network

A good strategy for developing parallel network models is to first create a scalable serial implementation, and then transform the implementation into a parallel form. The basic steps in constructing any network model are to define the cell types, create instances of the cells, and finally to connect them together. For our first example of how to do this with NEURON, we imagine 20 cells connected in a ring where cell i projects to cell i+1, and the last cell (cell 19) projects to the first cell (cell 0) (Fig. 3.1). For didactic purposes we give each cell some structure consisting of a soma and a dendrite, as in the classical ball and stick model (Fig. 3.2). The soma has Hodgkin-Huxley channels so that it can generate spikes. The dendrite is passive, with an excitatory synapse attached to it. Activating the synapse produces a large enough depolarization to trigger a somatic spike.
Fig. 3.1. A network of 20 ball and stick cells arranged in a ring. Each cell *i* makes an excitatory synaptic connection to the middle of the dendrite of cell *i*+1, except for cell 19 which projects back to cell 0.

Fig. 3.2. Left: A ball and stick model cell driven by an excitatory synapse at the middle of its dendrite. Right: Effects of weak and strong EPSPs on membrane potential `v` observed at the junction of the dendrite and soma, where a `NetCon` is attached whose `threshold` is 10 mV (dashed line). The strong EPSP elicits a spike, making `v` cross the `NetCon`'s threshold in a positive-going direction (arrow) so that an event will be sent to the `NetCon`'s target.

3.1 Define the cell type

To define a cell type, one would either write hoc code, or use the Network GUI tools as described in the tutorial at http://www.neuron.yale.edu/neuron/docs/netbuild/main.html, then export a hoc file and extract the cell type definition from it as described in chapter 11 of The

NEURON Book (Carnevale and Hines 2006). In either case, the essential elements of a cell type are its morphology and distributed membrane properties. It is also generally convenient to specify the location of the spike trigger zone, and the threshold for spike detection (see Fig. 3.2), which are almost always the same for all cells of a given type. This makes it easier to implement a `source.connect2target` procedure for connecting cells with simple syntax.

Synapses are a different matter. The question is whether, apart from toy networks, it is possible to construct all synapses with proper locations and types when a cell is created, without regard to what the connections are going to be. If synapse properties depend in any way upon the source cell type and location, it will be simpler to create the synapse at the same time as the `NetCon`. In any event, it is useful for each cell instance to have a list that holds the synaptic instances.

For this example we can just extract the template that defines the `B_BallStick` cell type from the tutorial example at http://www.neuron.yale.edu/course/net2/net2run_.hoc . Reading through the template (Listing 1), we find that it follows our recommendations with regard to specifying the spike trigger zone and detection threshold; `obfunc connect2target()` contains the statements

```
soma nc = new NetCon(&v(1), $o1)
nc.threshold = 10
```

which specify the variable and location that is monitored for occurrence of a spike (membrane potential `v` at the 1 end of `soma`, which also happens to be where the dendrite is attached), and the threshold at which the spike triggers an event (`v` rising above 10 millivolts). A bit farther into the listing, we discover that `proc synapses()` has this statement

```
/* E0 */   dend syn_ = new ExpSyn(0.8)  synlist.append(syn_)
```

where `synlist` is a public list that contains all synapses that are attached to a `B_BallStick` cell. In passing, we should mention that:

1. The reversal potential `e` of this `ExpSyn` is left unchanged from its default value of 0 mV, so we know that `ExpSyn` is excitatory.

2. `geom_nseg()` sets `dend.nseg` to 7 before `synapses()` is called (see `proc init()` for the execution sequence when a new `B_Ballstick` is created), so the `ExpSyn` is actually located at 0.78571429 instead of 0.8.

3. If we were developing *de novo*, it would be essential to verify that the anatomical and biophysical properties are correct and that the cell generates a spike when driven when

the excitatory synapse is activated. However, from the tutorial example, we already know that the `B_Ballstick` cell type works.

[Listing 1 near here]

3.2 Serial implementation of the network

Listing 2 is a program that implements and exercises the network model in a manner that is suitable for execution on serial hardware. For ease of development and debugging, the program has a modular structure with a sequence of procedures, each of which has a particular purpose, and it makes extensive use of lists so that collections of objects can be treated as sets (see chapter 11 in (Carnevale and Hines 2006)).

[Listing 2 near here]

In broad outline, it starts by following the natural sequence of defining the cell types that are involved, creating the instances of the cells, and then setting up the connections between them. The rest of the program is devoted to instrumentation (stimulating the network and recording the times at which cells fire), simulation control (launching a simulation for a specified time), and reporting simulation results (printing out which cell fired when).

We already discussed the definition of the cell type in the previous section. Since all cells are to exist on a single host, the remaining tasks are quite straightforward.

3.2.1 Creating and connecting the cells

A simple `for` loop in `proc mkcells()` is sufficient to create all instances of cells that will be part of the ring, and append them to a list called `cells`.

```
proc mkcells() {local i  localobj cell
  cells = new List()
  for i=0, $1-1 {
    cell = new B_BallStick()
    cells.append(cell)
  }
}
```

Another `for` loop in `proc connectcells()` iterates over the contents of this list to set up the network connections by creating a `NetCon` for each cell `i` that will drive the excitatory synapse on cell `i+1`, and wraps around so that the last cell in the ring drives the synapse on the first cell. These `NetCons` are appended to another list called `nclist`.

```
proc connectcells() {local i  localobj src, target, syn, nc
  nclist = new List()
  for i=0, cells.count-1 {  // iterating over sources
    src = cells.object(i)
    target = cells.object((i+1)%cells.count)
    syn = target.synlist.object(0)  // the first object in synlist
        // is an ExpSyn with e = 0, therefore an excitatory synapse
    nc = src.connect2target(syn)
    nclist.append(nc)
    nc.delay = 1
    nc.weight = 0.01
  }
}
```

Note that the iteration in `connectcells()` is *source-centric*, i.e. each new `i` is treated as the index of a source cell, so that the index of its target is i+1 modulo NCELL. We could just as easily have used a *target-centric* strategy by treating `i` as the index of a target, and found the index of the source as i-1 modulo NCELL. In either case, the computational effort would have been the same. However, in a parallel environment the choice of source-centric vs. target-centric iteration has a bearing on setup efficiency; we will return to this later.

3.2.2 Instrumentation and simulation control

Stimulation is achieved by `proc mkstim()`, which creates a `NetStim` that will generate a single spike event source and attaches it via a `NetCon` to the excitatory synapse on cell 0. Recording of spike times is set up by `proc spikerecord()`, which uses the `NetCon` class's `record()` method to capture spike times to a `Vector`. Simulation control makes use of the `run()` procedure which is part of NEURON's standard run system, and `proc spikeout()` handles printout of spike times.

3.3 Transforming the implementation from serial to parallel

A parallel implementation of the ring network is presented in Listing 3. Creating an instance of the `ParallelContext` class gives us access to the methods that support the ideas discussed in *2.2 Important concepts*. We will discuss these methods as they come up in the revised implementation of our model network.

Note the use of curly brackets around `load_file()` to suppress printing of superfluous 0s and 1s to standard output, as mentioned at the end of *2.1.2 Building and testing NEURON*. This has also been done to several `ParallelContext` method calls near the end of the listing.

[Listing 3 near here]

3.3.1 Creating the cell instances

For the sake of illustration, the parallel implementation of `mkcells()` is excerpted here with a **bold monospace** typeface that marks changes from the serial implementation.

```
proc mkcells() {local i  localobj cell, nc, nil
  cells = new List()
  // each host gets every nhost'th cell,
  // starting from the id of the host
  // and continuing until all cells have been dealt out
  for (i=pc.id; i < $1; i += pc.nhost) {
    cell = new B_BallStick()
    cells.append(cell)
    pc.set_gid2node(i, pc.id) // associate gid i with this host
    nc = cell.connect2target(nil) // attach spike detector to cell
    pc.cell(i, nc) // associate gid i with spike detector
  }
}
```

The `for` loop no longer iterates over all cells in the net; instead, on each host the `for` statement iterates `i` over just those gid values that belong on that host. In essence, this "deals out" the cells to the hosts, one at a time., so that the cells are distributed more or less evenly over the hosts. In the end, each host will have its own `cells` list, which will be about $1/N$ as long as the `cells` list in the serial implementation.

The `for` loop also associates each gid with a spike source on a particular host. In principle this could be done with a single primitive method, but for the sake of flexibility the process has been divided into three steps. First, we call `set_gid2node()` on the host that "owns" the cell to associate the cell's gid with the id of the host. Second, we create a temporary `NetCon` that specifies the location of the spike detector on the cell; this `NetCon` does not need to have a real target. Third, we use `pc.cell()` to associate the spike detector location with the gid. Note that the gid of a cell's spike detector will have the same value as the index of that cell in the `cells` list of the original serial implementation, and since there is only one spike detector per cell, we can use the gids to refer to individual cells. If the number of hosts is N, the mapping of cells to hosts will be as shown in Table 1.

host id	gid
0	$0, N, 2N \ldots$
1	$1, 1 + N, 1 + 2N \ldots$
$\vdots$	$\vdots$
N - 1	N - $1, 2N$ - $1, 3N$ - $1 \ldots$

Table 1. The mapping of cells to hosts in this example. There are *N* hosts whose ids range from 0 to *N* - 1, and the gids are the global identifiers of the cells.

3.3.2 Setting up the network connections

In the serial program, when we made connections between cells `i` and `i+1`, we were able to exploit the `cells` list as a map between index integers and the corresponding cell objects. This is not possible in the parallel implementation because the indices of `cells` no longer have that meaning; as noted above, each host has its own `cells` list, which contains just those cells that belong to that host.

Parallelizing this model requires several changes to `connectcells()`, all of which are direct consequences of the need to refer to cells by their gids instead of `cells` list indices (revisions indicated by **bold monospace** typeface).

```
proc connectcells() {local i, targid  localobj src, target, syn, nc
  nclist = new List()
  for i=0, NCELL - 1 {  // iterating over source gids
    targid = (i+1)%NCELL
    if (!pc.gid_exists(targid)) { continue }
    target = pc.gid2cell(targid)
    syn = target.synlist.object(0)  // the first object in synlist
        // is an ExpSyn with e = 0, therefore an excitatory synapse
    nc = pc.gid_connect(i, syn)
    nclist.append(nc)
    nc.delay = 1
    nc.weight = 0.01
  }
}
```

The first significant change is that the `for` statement, which iterates over all spike source gids, must use `NCELL` (the total number of cells in the net) instead of `cells.count` to specify the number of iterations.

The simple rule that defined the architecture of the ring network must now be expressed in terms of gids, hence `targid = (i+1)%NCELL` where `i` is the gid of a source and `targid` is the gid of the corresponding target. Also, before trying to set up a synaptic connection on any host, we verify that `targid` belongs to a cell that actually exists on that host by executing

```
if (!pc.gid_exists(targid)) { continue }
```

If the target cell does not exist, the remaining statements inside the `for` loop will be skipped. Otherwise, `gid2cell()` gets an `objref` for the cell, which is used to get an `objref` for the synapse that is to receive events from the spike source. The last change in `connectcells()` is to use `gid_connect()`, which creates a `NetCon` that conveys events from spike source gid `i` to target synapse `syn`.

Earlier we noted that the computational effort required to set up a serial implementation of this network was the same regardless of whether the `for` loop iterated over sources or targets. On parallel hardware, however, it is less efficient to iterate over sources. In this particular example, each host must iterate over all source gids in order to find the gids of the targets that exist. The penalty is small because it doesn't take that much time to increment `i` from 0 to `NCELL`-1, generate the target's gid, and check to see if that gid exists, but as a rule it is better for each host to iterate over the targets that exist on itself. Later in this paper we will present a strategy for doing this.

3.3.3 Instrumentation

As in the serial implementation, stimulation is accomplished by a `NetStim` that sends a single event to the excitatory synapse on the first cell in the net, i.e. the cell whose gid is 0. This `NetStim`, and the `NetCon` that delivers its event, need to exist only on the host that has the first cell, so we have inserted

```
if (!pc.gid_exists(0)) { return }
```

at the start of `proc mkstim()` so that nothing is done on the hosts that do not have this cell. We also changed the statement that creates the `NetStim` so that it uses gid 0 to retrieve the cell's `objref`

```
ncstim = new NetCon(stim, pc.gid2cell(0).synlist.object(0))
```

Also as in the serial implementation, the `NetCon` class's record method is used to capture the spiking of the ring network's cells into a pair of `Vectors`. However, each host can only record the spike times of the cells that exist on itself, so each host must have its own `tvec` and `idvec` to hold the spike times and corresponding cell gids. Furthermore, the `for` loop must iterate over all cells on any particular host, which is the same as all items in that host's `cells` list. Finally,

we must remember to record the cell's gid, which is unique to each cell, not its index `i` into the
`cells` list. Consequently the `record()` statement must be changed to

```
nc.record(tvec, idvec, nc.srcgid)
```

where the `NetCon` class's `srcgid` method is used to retrieve the gid of the spike source to which
a `NetCon` is attached.

3.3.4 Simulation control

With the serial implementation, it is only necessary to specify the duration `tstop` of a
simulation, and then call the standard run system's `run()`. In turn, `run()` calls `stdinit()`
which initializes the model, and `continuerun(tstop)` which carries out the simulation per se.

Simulations of distributed network models require replacing `run()` by three statements. The
first is `pc.set_maxstep()`, which examines all connections between cells on different hosts
(i.e. the delays of all `NetCon`s that were created by calling `gid_connect()`) to find the
minimum delay, then sets the maximum integration step size on every host to that value (but not
greater than the value of its second argument). The second statement is just `stdinit()` which
initializes the model, and the third is `pc.psolve(tstop)` which has an effect similar to
`cvode.solve(tstop)`, i.e. integrates until its step passes tstop, then interpolates the values of
the states at exactly `tstop` and calls the functions necessary to update the assigned variables.

3.3.5 Reporting simulation results

Simulations on parallel hardware are generally done in batch mode with no graphical user
interface, and typically produce a large volume of data that must be stored for later analysis. For
this toy example, we will just dump the spike times and cell gids to the terminal.

The serial version collects all spike times and cell ids in a pair of `Vector`s called `tvec` and
`idvec`, in the sequence in which the spikes occurred. The `spikeout()` procedure prints a
header, then uses a `for` loop to print out all contents of these `Vector`s, e.g.

```
time      cell
2.05      0
5.1       1
8.15      2
11.2      3
 . . .
93.55     10
96.6      11
99.65     12
```

However, in the parallel version each host has its own `tvec` and `idvec`, which can only capture the spike times and gids of the cells that exist on that host. Printing out these results requires a nested pair of `for` loops: the outermost iterates over the hosts, and the inner one iterates over the contents of the individual host's `tvec` and `idvec`. Special care must be taken or else each host will compete to print its own `tvec` and `idvec`, scrambling the printout because there is no guarantee as to which host starts printing first, nor is there any protection against one host's output stream being interrupted at any arbitrary point by the output stream from another host.

We can prevent this by forcing the parallel computer to emulate a serial computer while outputting simulation results. This is done with the `ParallelContext` class's `barrier()` method, which makes hosts that are racing ahead wait until all other hosts have caught up before proceeding further. The first `pc.barrier()` statement in `spikeout()` ensures completion of all printing that must be finished before the header is printed. The second one is the last statement in the outermost `for` loop, so that each host has sufficient time to finish printing its spike times. These changes are shown below in **bold monospace** typeface.

```
proc spikeout() { local i, rank
  pc.barrier() // wait for all hosts to get to this point
  if (pc.id==0) printf("\ntime\t cell\n") // print header just once
  for rank=0, pc.nhost-1 { // host 0 first, then 1, 2, etc.
    if (rank==pc.id) {
      for i=0, tvec.size-1 {
        printf("%g\t %d\n", tvec.x[i], idvec.x[i])
      }
    }
    pc.barrier() // wait for all hosts to get to this point
  }
}
```

The parallel version's printout will be grouped according to which cells are on which hosts, as in this run with four hosts

```
time     cell
2.05     0
14.25    4
26.45    8
38.65    12
 . . .
72.2     3
84.4     7
96.6     11
```

But all the spike times and cells are the same as in the serial implementation, as we can verify by capturing the outputs of the two programs to files, sorting the parallel output, and comparing

```
$ sort -g parout.txt > sorted_parout.txt
$ cmp serout.txt sorted_parout.txt
$
```

Further tests (results not shown) confirm that this program generates identical firing patterns regardless of the number of hosts. It also produces the same firing patterns when run on a single processor PC without MPICH2.

4. Second example: a network with random connectivity

A recurring theme in computational modeling is randomness, which may be manifested in the model specification (anatomical and biophysical attributes of cells, locations and properties of synapses, network topology and latencies of connections between cells) or as stochastic perturbations of variables in the course of a simulation (noisy voltage or current sources, fluctuation of model parameters such as ionic conductances, stochastic transmitter release or channel gating, spatiotemporally varying patterns of afferent spike trains). It is essential to achieve statistical independence of such parameters, while at the same time ensuring reproducibility--i.e. the ability to recreate any particular model specification and simulation--no matter how many hosts there are, or how the cells are distributed over them. Being able to generate quantitatively identical results on parallel or serial hardware is particularly important for debugging.

The key to achieving this goal is for each cell to have its own independent random number generator. This is the one thing that will be the same regardless of the number of hosts and the distribution of cells. To see how this is done with NEURON, let us consider a network with 20 cells in which each cell receives excitatory inputs from three other cells, chosen at random. The network is perturbed by an excitatory input to the "first" cell at t = 0. The cells and synapses are identical to those used in the first example (Fig. 3.2), so we can omit any discussion of cell types and focus on how to set up the network.

4.1 Serial implementation of the network

The problem of achieving reproducible, statistically-independent randomness can be solved by assigning each cell its own pseudorandom sequence generator, which is seeded with a unique integer so that the sequences will be independent. For this model, the sequences will be used to select the presynaptic sources that target each cell.

The final implementation of a program to create this network on serial hardware is presented in Listing 4. The general outline of this program is very similar to the serial implementation of the ring network, and many the details are identical (especially simulation control and reporting results). There are some cosmetic differences, e.g. the renaming of the `mkring()` procedure, which is now called `mknet()` and new parameter declarations, e.g. `C_E` which defines the number of excitatory inputs per cell, and `connect_random_low_start_` which is the lower 32 bit seed for the pseudorandom sequence generators that determine network connectivity. The most substantive changes, however, are those that we have focused on in the preceding paragraphs, which fall into two categories. The first category is code that introduces randomness into the network architecture. The second category, which is necessitated by the first, is code that analyzes and reports the network architecture. The following discussion examines these changes and the rationale behind them.

4.1.1 Planning ahead: verification of network architecture

Verification of network architecture is a critical test of reproducibility. The ring network was simple enough that we could write a program whose correctness could be determined almost by inspection. For a random net it is not enough to write code that purports to set up connections according to our plan; we must also make sure that the resulting network really does meet our design specifications. This can be done by exploiting the same `NetCons` that are used to set up the network connections. In the serial implementation, they are all contained in a single `nclist`, so we can iterate over the elements of this list and use the `NetCon` class's `precell()` and `syn()` methods to discover the identities of each spike source - target pair. What we really want, however, are the identities of the presynaptic cell, the synaptic mechanism that receives input events, and the postsynaptic cell to which that mechanism is attached. We can get these if we add "synapse id" and "cell id" variables to the synaptic mechanisms, and initialize the contents of these variables when each cell instance is created. With slight modification, this same strategy will work for the parallel implementation.

The original ball and stick model cell used the ExpSyn synaptic mechanism, so we make a local copy of nrn-6.0/src/nrnoc/expsyn.mod (c:\nrn60\src\nrnoc\expsyn.mod under MSWin), and change its NEURON block to

```
NEURON {
:        POINT_PROCESS ExpSyn
         POINT_PROCESS ExpSid
         RANGE tau, e, i, sid, cid
         NONSPECIFIC_CURRENT i
}
```

and change its PARAMETER block to

```
PARAMETER {
        tau = 0.1 (ms) <1e-9,1e9>
        e = 0    (mV)
        sid = -1 (1) : synapse id, from cell template
        cid = -1 (1) : id of cell to which this synapse is attached
}
```

(changes indicated in **bold monospace**). We also copy cell.hoc to a new file called cellid.hoc, then edit cellid.hoc to change each appearance of ExpSyn to ExpSid in the template that defines the B_BallStick class. Below in *4.1.4 Verifying network architecture* we will see how to use these changes to discover the architecture of a network after it has been set up.

4.1.2 Creating the cell instances

A first draft of the mkcells() procedure is very similar to what we used for the ring network, with two new statements that associate each cell with a pseudorandom sequence generator.

```
proc mkcells() {local i  localobj cell
  cells = new List()
  ranlist = new List()
  for i=0, $1-1 {
    cell = new B_BallStick()
    cells.append(cell)
    ranlist.append(new RandomStream(i))
  }
}
```

Every time a new cell is created and appended to the cells list, a corresponding object of the RandomStream class is also created and appended to a list called ranlist by the statement ranlist.append(new RandomStream(i)). The file ranstream.hoc, which is loaded near the beginning of the program, defines the RandomStream class plus an integer called random_stream_offset_ as shown here:

```
random_stream_offset_ = 1000

begintemplate RandomStream
public r, repick, start, stream
external random_stream_offset_
objref r
```

```
proc init() {
  stream = $1
  r = new Random()
  start()
}
func start() {
  return r.MCellRan4(stream*random_stream_offset_ + 1)
}
func repick() {
  return r.repick()
}
endtemplate RandomStream
```

From this we see that the `for i=0, $1-1 { }` loop in `mkcells()` creates a set of
`RandomStream` objects whose `MCellRan4` generators have highindex values which differ by
unique integer multiples of 1000. To quote from the entry on `MCellRan4` in NEURON's online
Programmer's Reference, "each stream should be statistically independent as long as the
highindex values differ by more than the eventual length of the stream". A difference of 1000 is
more than enough for our purpose, because it is only necessary to draw a few samples from each
cell's random stream in order to determine the three cells that drive its excitatory synapse. Note
that the argument to `r.MCellRan4` is 1 + `stream*random_stream_offset_`, which is
always > 0. This is necessary because an argument of 0 would result in the system automatically
choosing a highindex value that depends on the number of instances of the random generator that
have been created--an undesirable outcome that would defeat the reproducibility that we are
trying to achieve.

Of course we must also initialize the `sid` and `cid` variables that belong to the synaptic
mechanisms, as discussed in the previous section. This is done by inserting this `for` loop

```
for j=0, cell.synlist.count-1 {
  cell.synlist.o(j).sid = j
  cell.synlist.o(j).cid = i
}
```

after the `cells.append(cell)` statement in `mkcells()`. This inner loop iterates over all
synapses in a new cell's `synlist` to assign the appropriate values to their `sids` and `cids`.

4.1.3 Setting up the network connections

The algorithm for setting up this network's connections can be expressed in pseudocode as

```
for each cell c in the network {
    repeat {
```

          pick a cell *s* at random

          if *s* is not the same as *c* {

              if *s* does not already send spikes to the excitatory synapse *syn* on *c* {

                  set up a connection between *s* and *syn*

              }

          }

        } until 3 different cells drive *syn*

      }

Note that the network architecture lends itself naturally to a target-centric approach, so the outer loop iterates over target cells. This algorithm is implemented in `connectcells()`, which is excerpted here minus some "housekeeping" statements indicated by ellipses. Substantive differences from the ring network's `connectcells()` are in **`bold monospace`**.

```
proc connectcells() {local i, nsyn, r  localobj src, syn, nc, rs, u
  // initialize the pseudorandom number generator
  mcell_ran4_init(connect_random_low_start_)
  u = new Vector(NCELL)  // for sampling without replacement
  nclist = new List()
  for i=0, cells.count-1 {
    // target synapse is synlist.object(0) on cells.object(i)
    syn = cells.object(i).synlist.object(0)
    rs = ranlist.object(i)  // the corresponding RandomStream
    rs.start()
    rs.r.discunif(0, NCELL-1)  // return integer in range 0..NCELL-1
    u.fill(0)  // u.x[i]==1 means spike source i has already been chosen
    nsyn = 0
    while (nsyn < C_E) {
      r = rs.repick()
      // no self-connection, & only one connection from any source
      if (r != i) if (u.x[r] == 0) {
        // set up connection from source to target
        src = cells.object(r)
        nc = src.connect2target(syn)
        nclist.append(nc)
        nc.delay = 1
        nc.weight = 0.01
        u.x[r] = 1
        nsyn += 1
      }
    }
  }
}
```

The outer loop is a `for` loop that marches through the list of cells, one cell at a time. On each pass, the local object reference `syn` is made to point to the excitatory synapse of the current target cell, and the `u Vector`'s elements and the "connection tally" `nsyn` are all set to 0. The inner loop is a `while` loop that repeatedly

- picks a new random integer `r` from the range [0, `cells.count` - 1] until it finds an `r` that {is not the index of the current target cell} and {is not the index of a cell that has already been connected to `syn`}

- creates a new `NetCon` `nc` that connects cell `r`'s spike source to `syn`, and appends `nc` to `nclist`

- sets the corresponding element of the `u Vector` to 1 and increases the synapse count `nsyn` by 1

until `nsyn` equals the desired number of connections `C_E`.

4.1.4 Verifying network architecture

The network architecture is analyzed by `tracenet()`. This procedure iterates over each `NetCon` in `nclist` to retrieve and report the source cell id, target cell id, and target synapse id information for every network connection, using information that was stored in the network's cells and synaptic mechanisms at the time they were created.

```
proc tracenet() { local i  localobj src, tgt
  printf("source\ttarget\tsynapse\n")
  for i = 0, nclist.count-1 {
    src = nclist.o(i).precell
    tgt = nclist.o(i).syn
    printf("%d\t%d\t%d\n", src.synlist.o(0).cid, tgt.cid, tgt.sid)
  }
}
```

For our random net, the output of `tracenet()` is

```
source  target  synapse
12      0       0
16      0       0
17      0       0
9       1       0
16      1       0
 . . .
10      18      0
5       19      0
15      19      0
13      19      0
```

which immediately confirms that
- each target cell receives only three streams of spike events
- all events are delivered to the excitatory synapse
- there is no obvious regularity to the pattern of connectivity

4.1.5 Instrumentation, simulation control, and reporting simulation results

Here the only difference from the code used for the ring network is in the `spikerecord()` procedure. With the ring network, it was acceptable to let the `for` loop run from 0 to `nclist.count-1` because `nclist.count` was identical to `cells.count`. However, the random network has more connections than cells, so this loop must stop at `cells.count-1`.

4.2 A parallel implementation with reproducible randomness

As with the parallelized ring network model, the code starts by creating an instance of the `ParallelContext` class and uses curly brackets to suppress printing of unwanted results.

[Listing 5 near here]

4.2.1 Creating the cell instances

The parallelized `mkcells()` procedure for the random net is excerpted here, with differences from the serial implementation indicated by **bold monospace**.

```
proc mkcells() {local i  localobj cell, nc, nil
  cells = new List()
  ranlist = new List()
  gidvec = new Vector()
  for (i=pc.id; i < $1; i += pc.nhost) {
    cell = new B_BallStick()
    cells.append(cell)
    for j=0, cell.synlist.count-1 {
      cell.synlist.o(j).sid = j
      cell.synlist.o(j).cid = i
    }
    pc.set_gid2node(i, pc.id)  // associate gid i with this host
    nc = cell.connect2target(nil)  // attach spike detector to cell
    pc.cell(i, nc)  // associate gid i with spike detector
    ranlist.append(new RandomStream(i))  // ranlist.o(i) corresponds to
                                          //   cell associated with gid i
    gidvec.append(i)
```

```
  }
  report_gidvecs()
}
```

Most of these differences are similar to what we did with the ring network: a `for` loop deals out the cells across the hosts, so that each host gets every `nhost`'th cell, starting from the id of the host and continuing until no more cells are left. Each host has its own `cells` list to hold the cells that belong to it, plus a `ranlist` to hold the corresponding `RandomStream` objects. Two statements have been added so that each host also has a `Vector` called `gidvec`. The elements of `gidvec` are the gids that correspond to the cells in the cells list; in the next section we will see that this simplifies the task of setting up the network connections. Creating a cell involves appending it to the `cells` list, initializing the `sids` and `cids` that belong to its synapses, attaching a spike detector (`NetCon`) to it, associating a unique gid with the spike detector and with the host to which the cell belongs, creating a new `RandomStream` object and appending it to `ranlist`, and appending the gid to `gidvec`.

For the sake of debugging and development, we have added a purely diagnostic `report_gidvecs()` that is called at the end of `mkcells()`:

```
proc report_gidvecs() { local i, rank
  pc.barrier()  // wait for all hosts to get to this point
  if (pc.id==0) printf("\ngidvecs on the various hosts\n")
  for rank=0, pc.nhost-1 {  // host 0 first, then 1, 2, etc.
    if (rank==pc.id) {
      print "host ", pc.id
      gidvec.printf()
    }
    pc.barrier()  // wait for all hosts to get to this point
  }
}
```

This procedure prints out the gids of the cells that are on each host, one host at a time. With four hosts, the distribution of gids is

```
host 0
0       4       8       12      16
host 1
1       5       9       13      17
host 2
2       6       10      14      18
host 3
3       7       11      15      19
```

4.2.2 Setting up the network connections

We assembled `cells`, `ranlist`, and `gidvec` in tandem so that the *n*th element in each of these data structures corresponds to the *n*th elements in the other two. Consequently we can use the same index `i` to iterate over each cell on a host plus its associated `RandomStream` object and gid. This reduces the task of parallelizing `connectcells()` to making just two changes:

1. The test for "no self-connection and only one connection from any source" changes from

```
if (r != i) if (u.x[r] == 0) { }
```
   to
```
if (r != gidvec.x[i]) if (u.x[r] == 0) { }
```

2. Setting up a connection from source to target changes from

```
src = cells.object(r)
nc = src.connect2target(syn)
```
   to
```
nc = pc.gid_connect(r,syn)
```

4.2.3 Verifying network architecture

Most of the necessary revisions to `tracenet()` are required for the sake of orderly execution, and are similar to those that were necessary to parallelize the ring network's `spikeout()` procedure: in essence, using `ParallelContext barrier()` statements and iteration over hosts to reduce a parallel computer to a serial machine. The other change, which is needed because source cells may not be on the same host as their targets, consists of referring to the source cell by its gid, and affects two statements in `tracenet()` (indicated in **bold monospace**):

```
proc tracenet() { local i, rank, srcid  localobj tgt
  pc.barrier()  // wait for all hosts to get to this point
  if (pc.id==0) printf("source\ttarget\tsynapse\n")  // print header once
  for rank=0, pc.nhost-1 {  // host 0 first, then 1, 2, etc.
    if (rank==pc.id) {
      for i = 0, nclist.count-1 {
        srcid = nclist.o(i).srcgid()
        tgt = nclist.o(i).syn
        printf("%d\t%d\t%d\n", srcid, tgt.cid, tgt.sid)
      }
    }
    pc.barrier()  // wait for all hosts to get to this point
  }
}
```

On parallel hardware, the revised `tracenet()` prints out the connectivity information in a different sequence

```
source   target   synapse
12       0        0
16       0        0
17       0        0
1        4        0
0        4        0
2        4        0
10       8        0
0        8        0
 . . .
12       15       0
5        19       0
15       19       0
13       19       0
```

than it does on serial hardware, but sorting reveals that connectivity is identical regardless of the architecture of the computer on which it is run, and also identical to the connectivity produced by the serial implementation of this model.

4.2.4 Instrumentation, simulation control, and reporting simulation results

These are identical to the parallel implementation of the ring network. The serial implementation's spike times are reported in a monotonically increasing sequence

```
time      cell
2.05      0
5.1       16
5.1       8
 . . .
34.1      14
36.675    11
```

but, as with connectivity, the parallel implementation's output is grouped according to which cells are on which hosts

```
time      cell
2.05      0
5.1       4
5.1       8
 . . .
31.4      7
36.675    11
```

After capturing the spike times of the serial and parallel implementations to files and sorting them, comparison finds no difference in simulation results between the output of the serial or parallel implementations

```
$ sort -g serout.txt > sorted_serout.txt
$ sort -g parout.txt > sorted_parout.txt
$ cmp sorted_serout.txt sorted_parout.txt
$
```

regardless of whether the parallel code is run on serial hardware with or without MPICH2, or on parallel hardware under MPICH2 with any number of hosts.
